Abstract

We describe two BQP-complete problems concerning properties of sparse graphs having a certain symmetry. The graphs are specified by efficiently computable functions which output the adjacent vertices for each vertex. Let i and j be two given vertices. The first problem consists in estimating the difference between the number of paths of length m from j to j and those which from i to j, where m is polylogarithmic in the number of vertices. The scale of the estimation accuracy is specified by some a priori known upper bound on the growth of these differences with increasing m. The problem remains BQP-hard for regular graphs with degree 4.

The second problem is related to continuous-time classical random walks. The walk starts at some vertex j. The promise is that the difference of the probabilities of being at j and at i, respectively, decays

†e-mail: wocjan@cs.ucf.edu

with $O(\exp(-\mu t))$ for some $\mu > 0$. The problem is to decide whether this difference is greater than $a \exp(-\mu T)$ or smaller than $b \exp(-\mu T)$ after some time instant T, where T is polylogarithmic and the difference $a - b$ is inverse polylogarithmic in the number of vertices. Since the probabilities differ only by an exponentially small amount, an exponential number of trials would be necessary if one tried to answer this question by running the walk itself.

A modification of this problem, asking whether there exists a pair of nodes for which the probability difference is at least $a \exp(-\mu T)$, is QCMA-complete.

1 Introduction

Although it is commonly believed that quantum computers would enable us to solve several mathematical problems more efficiently than classical computers, it is difficult to characterize the class of problems for which this is expected to be the case. The class of problems which can be solved efficiently on a classical computer by a probabilistic algorithm is the complexity class BPP. The quantum counterpart of this complexity class is BQP, the class of problems that can be solved efficiently on a quantum computer with bounded error. Thus, the exact difference between the complexity classes BPP and BQP remains to be understood.

An important way of understanding a complexity class is to find problems which are complete for the latter. Meanwhile, some examples of BQP-complete problems are known [1, 2, 3, 4, 5]. For the results presented here, the ideas of [5] are crucial. We rephrase the main idea and proof of this article since they provide the basis for the present work. The problem is stated in terms of sparse matrices. Following [6, 7, 8], we call an $N \times N$ matrix A sparse if it has no more than $s = \text{polylog}(N)$ non-zero entries in each row and there is an efficiently computable function which specifies for a given row the non-zero entries and their positions.

We have formulated a decision problem concerning the estimation of the jth diagonal entry of the mth power of A and proved that it is BQP-complete. The proof that this problem is BQP-hard as well as the proof that it is in BQP both rely on the following observation. The jth diagonal entry of the mth power is the mth statistical moment of the probability distribution of outcomes when a measurement of the "observable" A is applied to the jth basis vector. Thus, the BQP-complete problem consists in estimating the probabilities of the outcomes in an A-measurement. Moreover, we have shown in [5] that the problem remains BQP-hard if it is restricted to matrices with entries $\pm 1, 0$.

It is not surprising that questions related to decompositions of vectors with respect to eigenspaces of large matrices lead to hard computational problems and that quantum computer could be more powerful in dealing with such problems. After all, the dynamics of a quantum system is determined by the spectral resolution of its initial state. In this context, the interesting questions and challenges are to determine to what extent it is possible to identify *natural* problems related to spectral resolutions which are not mere reformulations of questions about the dynamical behavior of quantum systems.

Calculating spectral decompositions with respect to large real symmetric matrices is certainly not a problem which only occurs in quantum theory. For example, methods in data analysis, machine learning, and signal processing rely strongly on the efficient solution of the principle component analysis [9]. However, data matrices typically occurring in these applications are in general not sparse and, even worse, their entries are usually not specified by an efficiently computable function. The data are rather given by observations.

In our opinion, it is an interesting challenge to construct BQP-problems concerning spectra of sparse matrices having only 0 and 1 as entries since problems of this kind are related to combinatorial problems in graph theory. It is quite natural to assume that a graph is sparse in the above sense; the efficiently computable function specifying the non-zero entries in each row is then a function which describes the set of neighbors of a given vertex and it is assumed that the number of neighbors is only polylogarithmic in the number of nodes.

The paper is organized as follows. In Section 2 we present a quantum algorithm for measuring functions of observables. This algorithm uses the quantum phase estimation algorithm as a subroutine. We use this algorithm to show that the problems "Diagonal Entry Estimation" (Section 3), "Difference of Number of Paths" (Section 4), and "Decay of Probability Differences" (Section 5) are all in BQP. Even though the first problem was already described in [5] we have first to extend these results in Section 3 since the proofs for the BQP-completeness of the other two problems are based on such an extension. In Section 4 we present a BQP-complete problem which (at first) strongly resembles the problem "Diagonal Entry Estimation". The important difference is that it deals with adjacency matrices (that is, 0-1-matrices) instead of matrices with entries ±1, 0. We describe how the problem is related to mixing properties of a classical random walk with discrete time. In Section 5 we describe a BQP-complete problem concerning the mixing properties of continuous-time classical random walks on regular sparse graphs. In Section 6 we describe a modification of the mixing problem which is QCMA-complete.

2 Measuring continuous functions of observables

Before we explain what it means to measure functions of observables we have to introduce some terminology. The spectral measure induced by a self-adjoint $N \times N$-matrix A and a state vector $|\psi\rangle \in \mathbf{C}^N$ is defined as the measure on $\mathbf{R}$ supported by the set of eigenvalues λ_j of A with probabilities $p_j := \langle\psi|Q_j|\psi\rangle$, where Q_j is the spectral projection corresponding to λ_j.

Let $f : \mathbf{R} \to \mathbf{R}$ be a function. The spectral measure induced by $f(A)$ and $|\psi\rangle$ is then the measure on $\mathbf{R}$ supported by the values $f(\lambda_j)$ with probabilities p_j, where p_j and λ_j are as above.

We define measuring a function f of an observable B in the state $|\psi\rangle$ as a quantum process which allows us to sample from a probability distribution that coincides with the spectral measure induced by $f(B)$ and $|\psi\rangle$. Note that when f is the identity function, then this corresponds what is considered to be a von-Neumann measurement of an observable in quantum mechanics. As in [5] the main tool for implementing such measurements is the quantum phase estimation algorithm [10]. The idea is that for each observable B with $\|B\| < \pi$ we can implement the measurement of B by applying quantum phase estimation to the unitary $\exp(iB)$, i.e., the map that describes the corresponding dynamics according to the Hamiltonian $-B$. For the class of self-adjoint operators considered here an efficient simulation of the dynamics is indeed possible since they are sparse [6, 7, 8]. By applying the procedure to a given state vector $|\psi\rangle$ we can sample from the spectral measure induced by B and $|\psi\rangle$.

The main statement of this section is that we can also sample from the spectral measure induced by $f(B)$ since we can implement such von-Neumann measurements of B and then apply f to the outcomes. Hence, no implementation of $\exp(if(B))$ is needed (this is important because, for sparse B, the matrix $f(B)$ will in general not be sparse and therefore it is not clear how to simulate the corresponding dynamics). In particular, we can estimate the expectation value of a given f with respect to the spectral measure. However, for our proofs it is essential how the accuracy behaves when certain smoothness assumptions are posed on f. This is made precise in Lemma 1.

But first we have to recall how quantum phase estimation works [10]. We add a p-qubit ancilla register to the n qubits on which $V := \exp(iB)$ acts. Then we replace the circuit implementing V with a controlled-V gate by replacing each elementary gate with its controlled analogue (note that this cannot be done in a black-box setting). The ancilla register is initialized to the equally weighted positive superposition of all binary words, then we use copies of the controlled gate to apply the 2^jth power of V to the n qubits if the jth ancilla qubit is in the state $|1\rangle$. Finally, we apply the inverse Fourier transform to the ancilla register and measure the ancillas in the computational basis. Given that the n-qubit register was in an eigenstate of V with eigenvalue $\exp(i2\pi\varphi)$ the obtained binary word $a \in \{0, 1, \ldots 2^p - 1\}$ provides a good estimation for $2\pi\varphi$ in the following sense:

$$\Pr(|\varphi - a/2^p| < \eta) > 1 - \theta\,, \tag{1}$$

where $\theta, \eta > 0$ and the number of ancillas is given by [11]

$$p := \lceil \log(1/\eta) \rceil + \lceil \log\left(2 + (1/(2\theta))\right) \rceil\,. \tag{2}$$

Here, the distance $|\varphi - a/2^p|$ is to be understood with respect to the cyclic topology of the unit circle which identifies $\varphi = 1$ with $\varphi = 0$. In contrast to the convention in [11] we reinterpret throughout the paper a as phases x in the interval $[-\pi, \pi)$ by defining $x := a\, 2\pi/2^p$ if $a \leq 2^{p-1}$ and $x := a\, 2\pi/2^p - 2\pi$ otherwise. We refer to x as the *outcome* of the measurement procedure. Then we have:

Lemma 1 (Continuous Functional Calculus)
Given a self-adjoint n-qubit operator B with $\|B\| \leq 1$ and a quantum circuit U with $\|U - \exp(iB)\| \leq \delta$ for some $\delta > 0$ such that the decomposition of U into elementary gates is known. Let $|\psi\rangle$ be an n-qubit state whose decomposition into B-eigenvectors contains only eigenvectors whose eigenvalues are in the closed (but possibly infinite) interval I. Let $f : I \to \mathbf{R}$ be a Lipschitz continuous function with constant K, i.e., $|f(x) - f(y)| \leq |x - y|\, K$ for all $x, y \in I$.

First, we apply the phase estimation (with unitary U) to $|\psi\rangle$, where the number p of ancilla qubits is given by eq. (2). Next, we apply f to the outcome x if $x \in I$, otherwise we replace x by the value in I closest to it and apply f to the latter. The expectation value of the random variable $f(X)$ in this experiment, denoted by $E_{|\psi\rangle}(f(X))$, satisfies

$$|E_{|\psi\rangle}(f(X)) - \langle\psi|f(B)|\psi\rangle| < (2\theta + \delta 2^{p+1})\, \|f\|_\infty + 2\pi K\eta\,,$$

where η, θ and p are related to each other as in eq. (2) and $\|f\|_\infty$ denotes the norm given by the supremum of $|f(x)|$.

Proof: We first assume we could implement $V := \exp(iB)$ instead of its approximation U. In this case, if we apply phase estimation to an eigenvector $|\psi_j\rangle$ of B with eigenvalue λ_j, then the outcome x is likely to be close to λ_j in the sense that

$$\Pr(|\lambda_j - x| < 2\pi\eta) > 1 - \theta\,.$$

This follows from ineq. (1) and the fact that the values $a/2^p$ have to be rescaled by 2π. We conclude

$$|E_{|\psi_j\rangle}(f(X)) - f(\lambda_j)| \leq 2\theta\|f\|_\infty + 2\pi K\eta\,. \qquad (3)$$

The second term on the right of ineq. (3) corresponds to the case that x deviates from λ_j by at most $2\pi\eta$ (note that the probability for this event is not decreased by replacing all outcomes lying outside from I with the closest values in I). Then the Lipschitz condition ensures that the error of $f(x)$ is small. If the error of x is large (which happens with probability at most θ), the error of $f(x)$ is still upper bounded by $2\,\|f\|_\infty$. If we replace the eigenvectors $|\psi_j\rangle$ with some vector $|\psi\rangle = \sum_j c_j|\psi_j\rangle$, the distribution of outcomes in the phase estimation procedure is a mixture of the distributions for each $|\psi_j\rangle$ with weights $|c_j|^2$. This is easily checked by analyzing the standard phase estimation. Thus we obtain

$$|E_{|\psi\rangle}(f(X)) - \langle\psi|f(B)|\psi\rangle| \leq 2\theta\|f\|_\infty + 2\pi K\eta\,. \qquad (4)$$

from ineq. (3) by convexity arguments.

Now we take into account that we have only an approximation U of V. Since the procedure uses $2^{p+1} - 1$ copies of the controlled-U respective, controlled-V, the norm distance between the phase estimation circuits is less than $2^{p+1}\delta$. Let $q(a)$ and $\tilde{q}(a)$ denote the probability of obtaining the result a when the phase estimation is implemented with U and V, respectively. Then the l^1-distance between the measures q and $\tilde{q}$ satisfies (for technical details see [5])

$$\|q - \tilde{q}\|_1 := \sum_a |q(a) - \tilde{q}(a)| \leq 2^{p+2}\,\delta\,.$$

The error in the expectation value of $f(X)$ caused by applying f to outcomes x computed from a when a is sampled according to $\tilde{q}$ instead of q is hence less than $2^{p+2}\,\delta\,\|f\|_\infty$.

Putting everything together we obtain the desired bound

$$|E_{|\psi\rangle}(f(X)) - \langle\psi|f(B)|\psi\rangle| < (2\theta + 2^{p+2}\,\delta)\,\|f\|_\infty + 2\pi K\eta\,. \tag{5}$$

Since we have shown that the expectation value of the values $f(x)$ in the procedure in Lemma 1 is close to the expectation value $\langle\psi|f(B)|\psi\rangle$ we can use the average over the values $f(x)$ after a small number of runs as a good estimate for the desired expectation value. The following lemma states that we obtain an efficient procedure for giving an estimation up to any desired accuracy which is inverse polynomial in n.

Lemma 2 (Estimation of Expectation Values)
Given an efficient algorithm to simulate $\exp(iB)$ *on n qubits with* $\|B\| \leq 1$ *in the sense that the resources to obtain a circuit U with* $\|U - \exp(iB)\| \leq \delta$ *scale polynomially in n and $1/\delta$. Given a state $|\psi\rangle$ whose decomposition into B-eigenvectors contains only those with eigenvalues in the interval I. Let f be as in Lemma 1. Then we can estimate $\langle\psi|f(B)|\psi\rangle$ up to an error $\epsilon \cdot (\|f\|_\infty + K)$ with probability at least $1-\alpha$ such that the time and space resources are bounded by a polynomial in n, $1/\epsilon$, and* $\log(1/\alpha)$.

Proof: The empirical average of the values $f(x)$ obtained after a few runs converges exponentially fast to the expectation value $E_{|\psi\rangle}(f(X))$. Using Hoeffding's bound [12] and the fact that $f(X)$ is a random variable with bounded range (for details cp. also [5]) one can easily show that the required number of runs for estimating then expectation value up to an accuracy ϵ scales inverse polynomial in ϵ and polylogarithmically in $1/\alpha$ when this error should be guaranteed with probability $1-\alpha$.

It remains to bound the resources required to ensure that

$$|E_{|\psi\rangle}(f(X)) - \langle\psi|f(B)|\psi\rangle| < \epsilon \cdot (\|f\|_\infty + K)\,.$$

Taking into account that the number of required ancilla qubits p is only logarithmic in $1/\theta$ and $1/\eta$ (see eq. (2)), ineq. (5) shows that the error is bounded by $(\|f\|_\infty + K)$ times a polynomial in $1/\theta$, $1/\eta$, $1/\delta$ and n.

In order to make the overall error smaller than $\epsilon \cdot (|f(I)| + K)$ we ensure that each of the three terms $2\theta \, \|f\|_\infty$, $2^{p+1} \, \delta \, \|f\|_\infty$, and $2\pi K \eta$ on the rhs. of ineq. (5) is at most $\epsilon \cdot (|f(I)| + K)/3$.

To this end, we choose $\eta = \epsilon/(6\pi)$ and $\theta := \epsilon/6$. Putting these values into eq. (2) we obtain the number of required ancilla qubits p. We choose δ such that $\delta \, 2^{p+2} \leq \epsilon/3$. Note that 2^p is polynomial in $1/\epsilon$, so that $1/\delta$ is polynomial in $1/\epsilon$ and n. The number of controlled-U circuits is a multiple of 2^p and, thus, only polynomial in $1/\epsilon$.

Lemma 2 shows that there is an efficient quantum algorithm for measuring functions of observables provided that the demanded accuracy is not too high. In the following sections we introduce several problems and prove that they are BQP-complete. The proofs that they are in BQP rely on the quantum algorithm for measuring functions of observables.

3 Diagonal Entry Estimation

In this section we extend the results of [5] saying that the estimation of diagonal entries of A^m for a sparse matrix with entries $\pm 1, 0$ is BQP-complete. Here we argue that the construction in [5] shows also that the problem remains BQP-hard if when further restricting to matrices with only 4 non-zero entries. This is made precise in Lemma 3.

Furthermore, Section 2 makes it possible to provide a unifying picture of the results in [5] and our results presented in Sections 4 and 5 since for all three problems we use spectral measures of functions of observables to show that they are in BQP.

We first state the formal definition of the decision problem related to the estimation of the diagonal entries of powers of sparse matrices.

Definition 1 (Diagonal Entry Estimation)
Given a sparse symmetric $N \times N$-matrix A with real entries, an integer $j \in \{1, \ldots, N\}$, and a positive integer $m = \mathrm{polylog}(N)$, estimate the diagonal entry $(A^m)_{jj}$ in the following sense:

Decide if either

$$(A^m)_{jj} \geq g + \epsilon \, b^m$$

or

$$(A^m)_{jj} \leq g - \epsilon\, b^m \,,$$

for given $g \in [-b^m, b^m]$ *and* $\epsilon = 1/\mathrm{polylog}(N)$*, where* b *is an a priori known upper bound on the operator norm of* A*.*

We showed in [5]:

Theorem 1 *The problem "Diagonal Entry Estimation" is BQP-complete. This remains true if the matrices* A *have only* $\pm 1, 0$ *as entries.*

We recall the formal definition of the complexity class BQP [13].

Definition 2 (The class BQP)
A language L *is in BQP if and only if there is a uniformly generated family of quantum circuits* Y_r *acting on* $\mathrm{poly}(r)$ *qubits that decide if a string* $\mathbf{x}$ *of length* r *is contained in* L *in the following sense:*

$$Y_r|\mathbf{x}, \mathbf{0}\rangle = \alpha_{\mathbf{x},0}|0\rangle \otimes |\psi_{\mathbf{x},0}\rangle + \alpha_{\mathbf{x},1}|1\rangle \otimes |\psi_{\mathbf{x},1}\rangle \tag{6}$$

such that

1. $|\alpha_{\mathbf{x},1}|^2 \geq 2/3$ *if* $\mathbf{x} \in L$ *and*
2. $|\alpha_{\mathbf{x},1}|^2 \leq 1/3$ *if* $\mathbf{x} \notin L$ *.*

Equation (6) has to be read as follows. The input string $\mathbf{x}$ *determines the first* r *bits. Furthermore,* l *additional ancilla bits are initialized to* 0*. After* Y_r *has been applied we interpret the first qubit as the relevant output and the remaining* $r + l - 1$ *output values are irrelevant. The size of the ancilla register is polynomial in* r*.*

To show that "Diagonal Entry Estimation" is in BQP we simply apply the quantum algorithm for measuring functions of the observable A/b to the state $|j\rangle$, and the function $f : [-1, 1] \to \mathbf{R}$ with $f(x) := x^m$. Then we can use Lemma 2 to show that we can efficiently estimate $\langle j|A^m|j\rangle$ with sufficient accuracy. To see this, we observe that the Lipschitz-constant K satisfies $K \leq m$ and we have $\|f\|_\infty = 1$. Hence we can efficiently estimate the diagonal entries of $(A/b)^m$ up to $\epsilon\,(m+1)$ for any desired inverse polynomial ϵ. With $\epsilon' := \epsilon\,(m + 1)$ we have an accuracy ϵ'. Thus, we may achieve an accuracy of $\epsilon'\, b^m$ for the diagonal entries of A^m for any desired inverse

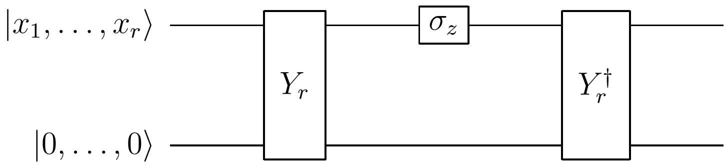

Figure 1: Circuit U constructed from the original circuit Y_r. Whenever the answer of the BQP problem is no, the output state of U is close to the input state $|\mathbf{x},\mathbf{0}\rangle \equiv |x_1,\ldots,x_n,0,\ldots,0\rangle$. Otherwise, the state $|\mathbf{x},\mathbf{0}\rangle$ is only restored after applying U twice.

polynomial ϵ'. By Definition 1, this is sufficient to solve "Diagonal Entry Estimation".

The idea of our proof of the BQP-hardness is based on an encoding of the quantum circuit which solves a given BQP-problem into a self-adjoint operator A such that the spectral measure induced by A provides the information on the solution. To this end, we assume that we are given a quantum circuit Y_r which decides whether a string $\mathbf{x}$ is in the given language L in the sense of Definition 2.

In some analogy to [14, 4] we construct a circuit U which is obtained from Y_r as follows: first apply the circuit Y_r, then apply the σ_z-gate on the output qubit, and finally apply the circuit $Y_r^\dagger$. The resulting circuit U is shown in Fig. 1. We denote the dimension of the Hilbert space U acts on by $\tilde{N}$.

Let U be generated by a concatenation of the M elementary gates

$$U_0,\ldots,U_{M-1}\,.$$

We assume furthermore that M is odd, which is automatically satisfied if we decompose $Y_r^\dagger$ in analogy to Y_r and implement a σ_z-gate between Y_r and $Y_r^\dagger$. We define the unitary

$$W := \sum_{l=0}^{M-1} |l+1\rangle\langle l| \otimes U_l\,, \tag{7}$$

acting on $\mathbf{C}^M \otimes \mathbf{C}^{\tilde{N}}$. Here the + sign in the index has always to be read modulo M.

Now we define the self-adjoint operator

$$A := \frac{1}{2}(W + W^\dagger)\,. \tag{8}$$

Then we apply an A-measurement to the state

$$|s_{\mathbf{x}}\rangle := |0\rangle \otimes |\mathbf{x}, \mathbf{0}\rangle \,.$$

Since $|s_{\mathbf{x}}\rangle$ is a basis state, we can choose j such that $|j\rangle = |s_{\mathbf{x}}\rangle$. To understand why $|\alpha_0|$ influences the measurement statistics it is useful to consider the extreme cases $|\alpha_1| = 0, 1$. One may check that the repeated application of W to $|j\rangle$ leads for $\alpha_0 = 0$ to an orbit (of mutually orthogonal states) that is periodic after M steps. The spectral measure induced by $|j\rangle$ and W is hence the uniform distribution over the Mth roots of unity. For $|\alpha_1| = 1$ the orbit is M-periodic up to the phase -1. This leads to a uniform distribution over the roots of unity reflected at the imaginary axis. As shown in [5] in detail, the spectral measure induced by $|j\rangle$ and A depends therefore on α_0, α_1 in the following way:

The spectral measure is the convex sum

$$P := |\alpha_0|^2 P^{(0)} + |\alpha_1|^2 P^{(1)} \,, \tag{9}$$

where $P^{(0)}$ is supported by the values $\lambda_l^{(0)} := \cos(2\pi l/M)$ with probabilities $P_l^{(0)} = 1/M$ for $l = 0$ and $P_l^{(0)} = 2/M$ for $l = 1, \dots, M - 1/2$. The measure $P^{(1)}$ is obtained from $P^{(0)}$ by a reflection at the origin and is hence supported by the values $\lambda_l^{(1)} := \cos(\pi(2l+1)/M)$ with probabilities $P^{(1)}_{(M-1)/2} = 1/M$ and $P_l^{(1)} = 2/M$ for $l < (M-1)/2$. The measure P can also be written as

$$P(\lambda) := \sum_l (|\alpha_0|^2 \delta_{\lambda,\lambda_l^{(0)}} P_l^{(0)} + |\alpha_1|^2 \delta_{\lambda,\lambda_l^{(1)}} P_l^{(1)}) \,. \tag{10}$$

Then we obtain the jth diagonal entry of A^m as the mth moment of the measure P:

$$\begin{aligned} (A^m)_{jj} &= \sum_\lambda \lambda^m \, P(\lambda) \\ &= (1 - |\alpha_1|^2) \sum_l \left(\lambda_l^{(0)}\right)^m P_l^{(0)} + |\alpha_1|^2 \sum_l \left(\lambda_l^{(1)}\right)^m P_l^{(1)} \,. \end{aligned} \tag{11}$$

Since the possible range of $|\alpha_1|$ is determined by the solution of the decision problem the latter also determines the range of the possible values for $(A^m)_{jj}$. One checks easily that $(A^m)_{jj}$ changes sufficiently when changing $|\alpha_1|$, i..e, an estimation of $(A^m)_{jj}$ makes it possible to decide whether $\mathbf{x} \in L$.

To see that the proof of BQP-hardness works also with matrices having only $\pm 1, 0$ as entries we make the following observation. Hadamard-gates and Toffoli-gates form a universal set. In [5] we have instead chosen a universal set containing only Hadamard gates and gates which are concatenations of one Hadamard gate with a Toffoli gate. Then the above unitaries U_l have only $\pm 1/\sqrt{2}$ as entries. Since the decision problem Diagonal Entry Estimation is formulated in a scale invariant way, we may rescale A by $\sqrt{2}$ and obtain only entries $\pm 1, 0$.

In the following we will need the following extension of the results in [5]:

Lemma 3 *The problem Diagonal Entry Estimation remains BQP-hard if A contains only entries* $\pm 1, 0$ and *the number of non-zero entries in each row of A is* 4*.*

The proof is obvious after observing that A as constructed above has exactly 4 nonzero entries in each column and, similarly, in each row. Each gate U_l has exactly two non-zero entries since it is the embedding of either a Hadamard gate or a Hadamard gate combined with a Toffoli gate. One checks easily that W has also two non-zero entries in each row leading to four entries in $W + W^\dagger$.

4 Difference of Numbers of Paths

In this section we show that a modified version of Diagonal Entry Estimation is still BQP-complete when restricting to matrix with entries $1, 0$. This makes the problem more combinatorial than the original one. In other words, we introduce a problem concerning regular sparse graphs and show that it is BQP-complete. A graph G is called regular if the degrees of all its vertices are equal. We call G sparse if its adjacency matrix $\tilde{A}$ is sparse, i.e., for each vertex the number of adjacent vertices is polylogarithmic in the number of nodes and there is an efficiently computable function that computes the set of adjacent vertices for each vertex. We define the following problem:

Definition 3 (Difference of Numbers of Paths)
Let $\tilde{A}$ be the adjacency matrix of a regular sparse graph G on N vertices and m a positive integer $m = \mathrm{polylog}(N)$. Let q and r be two vertices such that there exists an automorphism of G which exchanges q and r. Set

$$\Delta_{qr}^{(m)} := (\tilde{A}^m)_{qq} - (\tilde{A}^m)_{qr} \,.$$

Decide if either

$$\Delta_{qr}^{(m)} \geq g + \epsilon\, b^m$$

or

$$\Delta_{qr}^{(m)} \leq g - \epsilon\, b^m\,,$$

for given $g \in [-b^m, b^m]$ *and* $\epsilon = 1/\text{polylog}(N)$*, where* b *is an a priori known upper bound on*

$$\sup_n |\Delta_{qr}^{(n)}|^{1/n}\,.$$

Theorem 2 *The problem "Difference of Numbers of Paths" is BQP-complete.*

We prove this theorem by showing that this problem is BQP-hard and is contained in BQP. The proof of BQP-hardness is based on a reduction to the problem "Diagonal Entry Estimation". An efficient quantum algorithm for estimating the difference of number of paths is obtained by applying the algorithm for measuring functions of observables.

4.1 "Difference of Numbers of Paths" is BQP-hard

We show that "Diagonal Entry Estimation" reduces to "Difference of Number of Paths". Let A be an $N \times N$ matrix with entries $\pm 1, 0$ as in Definition 1. The reduction relies on the conversion of A into a 0-1-matrix $\tilde{A}$ acting on a space of dimension $D := 2N$ such that the restriction of $\tilde{A}$ to some invariant N-dimensional subspace is unitarily equivalent to A.

The conversion works as follows. Each -1 in A is replaced by the Pauli-matrix σ_x and each 1 by the identity matrix $\mathbf{1}_2 = \sigma_x^2$. Each 0 is replaced by the zero matrix $\mathbf{0}_2$. More formally, the ±1-0-matrix

$$A = \sum_{i,j=0}^{N-1} a_{ij} |i\rangle\langle j|$$

is converted to the 0-1-matrix

$$\tilde{A} := \sum_{i,j=0}^{N-1} \gamma_{ij} \otimes |i\rangle\langle j|\,,$$

where $\gamma_{ij} := \sigma_x$ if $a_{ij} = -1$, $\gamma_{ij} := \mathbf{1}_2$ if $a_{ij} = 1$, and $\gamma_{ij} := \mathbf{0}_2$ if $a_{ij} = 0$.

We now prove that the restriction of $\tilde{A}$ to some N-dimensional subspace is unitarily equivalent to A. To this end, we start by introducing the vectors

$$|\phi^\pm\rangle := \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle) \in \mathbf{C}^2 .$$

On the subspace spanned by $|\phi^-\rangle$ the matrices γ_{ij} act by multiplying the vectors by the scalars a_{ij}, i.e.,

$$\gamma_{ij}|\phi^-\rangle = a_{ij}|\phi^-\rangle .$$

Similarly, on the subspace spanned by $|\phi^+\rangle$ they act by multiplying the vectors by the scalars $|a_{ij}| = a_{ij}^2$, i.e.,

$$\gamma_{ij}|\phi^+\rangle = a_{ij}^2|\phi^+\rangle .$$

Consequently, we have the direct sum decomposition

$$\tilde{A} = |\phi^-\rangle\langle\phi^-| \otimes A + |\phi^+\rangle\langle\phi^+| \otimes (A * A) ,$$

where $A*A$ is the Hadamard product (or entry-wise product) of A with itself and has therefore only $0, 1$ as entries. In the following, it will be important that $\tilde{A}$ is invariant under conjugation with $\sigma_x \otimes \mathbf{1}_N$. This invariance follows directly from the direct sum decomposition and the fact the vectors $|\phi^\pm\rangle$ are eigenvectors of σ_x with corresponding eigenvalues ±1.

Assume we want to estimate $(A^m)_{jj}$. Let $|j\rangle$ be the jth basis vector in $\mathbf{C}^N$. Then we define vectors in $\mathbf{C}^2 \otimes \mathbf{C}^N \equiv \mathbf{C}^{2N}$ by $|\psi^-\rangle := |\phi^-\rangle \otimes |j\rangle$, $|q\rangle := |0\rangle \otimes |j\rangle, |r\rangle := |1\rangle \otimes |j\rangle$, and label the corresponding vertices by q and r, respectively. We have then $|\psi^-\rangle = (|q\rangle + |r\rangle)/\sqrt{2}$. Note that the automorphism $\sigma_x \otimes \mathbf{1}$ exchanges the vertices q and r. We reproduce diagonal entries of A^m from both diagonal and off-diagonal entries of $\tilde{A}^m$ as follows:

$$\begin{aligned} (A^m)_{jj} &= \langle\psi^-|\tilde{A}^m|\psi^-\rangle \\ &= \sqrt{2}\langle\psi^-|\tilde{A}^m|q\rangle \\ &= (\tilde{A}^m)_{qq} - (\tilde{A}^m)_{qr} = \Delta_{qr}^{(m)} . \end{aligned} \tag{12}$$

The second equality follows from the fact that the space $|\phi^-\rangle \otimes \mathbf{C}^N$ is $\tilde{A}$-invariant. Thus, only the component of $|q\rangle$ lying in this subspace is relevant.

The terms in eq. (12) correspond to the number of paths of length m from q to q and from q to r, respectively. In other words, the problem of estimating diagonal entries of A^m reduces to estimating the number of paths of length m from q to q and q to r in the graph defined by $\tilde{A}$, where q and r have to be chosen suitably.

Taking into account that also off-diagonal entries of powers of sparse matrices can be estimated efficiently [5], it seems as if we had already shown that estimating entries of powers of adjacency matrices is BQP-complete. However, this is not the case. There is a subtle but very important issue concerning the precision of this estimation. The accuracy in Definition 1 is given by $\epsilon\, b^m$, where b is an a priori known bound on the operator norm of A. In general, this bound will not be a bound on the norm of $\tilde{A}$. Using the direct sum decomposition of $\tilde{A}$, we see that the norm of $\tilde{A}$ is equal to $\max\{\|A\|, \|A{*}A\|\}$ and is smaller or equal to $\max\{b, b^2\}$ as $\|A{*}A\| \leq \|A{\otimes}A\|$ [15]. On the one hand, if we estimate the entries of $\tilde{A}^m$ up to an accuracy specified in terms of the norm of $\tilde{A}$, then these values are not good enough to obtain a sufficiently precise estimate of the diagonal entry $(A^m)_{jj}$. Assume for instance, that $c\|A\| = \|\tilde{A}\|$ for some constant $c > 1$. Then the entries of $\tilde{A}$ can only be estimated with an accuracy that is an inverse polynomial multiple of $c^m\|A\|^m$, which is exponentially worse than the required accuracy $\epsilon\,\|A\|^m$. On the other hand, the operator norm $\|A\|$ of A is not a natural quantity to define the required accuracy of the estimation of the number of paths in $\tilde{A}$.

For these reasons the estimation accuracy of the decision problem "Difference of Numbers of Paths" is not (and should not be) formulated in terms of the norm of $\tilde{A}$. Instead, it is specified in terms of a quantity which is sufficiently small, making it possible to reduce Diagonal Entry Estimation to the former. For doing so, we recall that for each $n \in \mathbf{N}$ the nth diagonal entry of A^n can be expressed in terms of $\Delta_{qr}^{(n)}$ due to

$$(A^n)_{jj} = \Delta_{qr}^{(n)}\,.$$

We have therefore

$$\sup_{n\in\mathbf{N}} |\Delta_{qr}^{(n)}| = \sup_{n\in\mathbf{N}} |\langle\psi^-|\tilde{A}^n|\psi^-\rangle| = \sup_{n\in\mathbf{N}} |(A^n)_{jj}| \leq \|A\|^n\,.$$

This proves that if we can solve "Difference of Number of Paths" then we can also decide between the two cases in Definition 1 with $b := \|A\|$.

It remains to show that $\tilde{A}$ is the adjacency matrix of a *regular* graph. We first recall Lemma 3. By replacing the values ±1 with the 2×2 identity matrix and the matrix σ_x, respectively, we obtain a matrix with four entries in each row, as well. Hence all vertices of the graph have degree 4.

4.2 "Difference of Number of Paths" is in BQP

To solve the problem "Difference of Numbers of Paths" on a quantum computer we observe that $\Delta_{pr}^{(m)}$ is an expectation value of a random variable which occurs in an appropriate measurement procedure. In analogy to the preceding paragraph, we define

$$|\psi^-\rangle := \frac{1}{\sqrt{2}}(|q\rangle + |r\rangle)\,,$$

with the essential difference that the nodes q and r are a priori given and not derived from setting $|q\rangle := |0\rangle \otimes |j\rangle$ and $|r\rangle := |1\rangle \otimes |j\rangle$. Then we have nevertheless

$$\Delta_{qr}^{(m)} \quad = \quad \langle\psi^-|\tilde{A}^m|\psi^-\rangle\,, \tag{13}$$

which follows here from the symmetry defined by the given graph automorphism. Without this symmetry, we had

$$\langle\psi^-|\tilde{A}^m|\psi^-\rangle = \frac{1}{2}(\Delta_{qq}^{(m)} - 2\Delta_{qr}^{(m)} + \Delta_{rr}^{(m)})\,,$$

but here we have $\Delta_{qq}^{(m)} = \Delta_{rr}^{(m)}$. Due to the promise on the growth of $\Delta_{qr}^{(n)}$ the decomposition of $|\psi^-\rangle$ in $\tilde{A}$-eigenvectors contains only those eigenvectors whose corresponding eigenvalues satisfy $\lambda_j \in [-b, b]$. We may rescale $\tilde{A}$ by some factor d such that its norm is at most 1. On the rescaled interval $[-b/d, b/d]$ we define the function $f(x) := x^m$ having Lipschitz-constant $K \leq m(b/d)^m$ and sup-norm $\|f\|_\infty = (b/d)^m$. Then the achievable estimation error for $\langle\psi^-|(\tilde{A}/d)^m|\psi^-\rangle = \Delta_{qr}^{(m)}/d^m$ is an inverse polynomial multiple of $(b/d)^m$, i.e., we can estimate $\Delta_{qr}^{(m)}$ up to any desired inverse polynomial multiple of b^m.

4.3 Interpretation of difference of number of paths in terms of discrete-time random walks

Note that there is also an alternative interpretation for the difference of the number of paths. Since $\tilde{A}$ describes a regular graph of degree 4, we obtain a doubly stochastic matrix by

$$\hat{A} := \frac{1}{4}\tilde{A}\,.$$

It describes a classical random walk (in discrete time) on the corresponding graph. Then the entry $(\hat{A}^m)_{ij}$ is the probability of reaching position j after m steps given that the initial position was i. For increasing m, the difference $(\hat{A}^m)_{ii} - (\hat{A}^m)_{ij}$ is therefore directly linked to the decay of probability differences, i.e., to mixing properties of the random walk.

5 Decay of Probability Differences

We can also formulate a BQP-complete problem in term of *continuous-time* random walks on regular sparse graphs. The dynamics of a random walk is generated by the Laplacian of the underlying graph. Consequently, the time evolution of an initial probability distribution is determined by its spectral resolution into the eigenvectors of the Laplacian.

For regular graphs, the Laplacian coincides with the adjacency matrix up to the negative sign and an additive multiple of the identity matrix. Hence, the spectral resolution with respect to the adjacency matrix (being crucial in the preceding section) also determines the behavior of the continuous random walk. We introduce some notation to make these statements more precise.

Let $\tilde{A}$ describe a regular graph on N vertices with degree d. We define its Laplacian by [16]

$$\mathcal{L} := d\,\mathbf{1} - \tilde{A}\,.$$

Let $p(t) = (p_1(t), \ldots, p_N(t))$ be a probability distribution where $p_j(t)$ for $j = 1, \ldots, N$ is the probability of being at vertex j for $j = 1, \ldots, N$. The Laplacian $\mathcal{L}$ defines a continuous-time (classical) random walk by

$$p(t) := e^{-\mathcal{L}t} p\,,$$

where $p = p(0)$ is the initial probability distribution.

Our BQP-complete problem considers the following question. Assume that the random walk starts at vertex q. Given a second vertex r, determine the decay of the difference between the probabilities $p_q(t)$ and $p_r(t)$.

For infinite time, only the smallest eigenvalue whose eigenvector is contained in the initial state p determines the exponent dominating the decay. For our specific problem (where only the difference between the probabilities of two vertices is considered), only the spectral decomposition of $|q\rangle - |r\rangle$ is relevant. For a random walk which started at vertex q, the difference between $p_q(t)$ and $p_r(t)$ is given by

$$c_{qr}(t) := (e^{-\mathcal{L}t})_{qq} - (e^{-\mathcal{L}t})_{qr}\,, \tag{14}$$

where we use $(W)_{qr}$ to denote the entry of an arbitrary matrix W in row q and column r.

Our BQP-complete problem is defined as follows.

Definition 4 (Decay of Probability Differences)
Let $c_{qr}(t)$ be defined as in eq. (14), where $\mathcal{L}$ is the Laplacian of a regular graph G on N vertices with degree $d \in O(\mathrm{polylog}(N))$ such that there is an efficiently computable function that determines the set of adjacent vertices for every vertex. Let $\mu > 0$ and $b < a < 1$ be two positive numbers with $1/a, 1/b, 1/(a-b) \in \mathrm{polylog}(N)$ and $T \in \mathrm{polylog}(N)$ be some time instant. Let q, r be two vertices for which there is an automorphism of G exchanging q and r. Given the promise that

$$c_{qr}(t) \in O(e^{-\mu t}) \,,$$

decide if either

$$c_{qr}(T) \geq a\, e^{-\mu T}$$

or

$$c_{qr}(T) \leq b\, e^{-\mu T} \,.$$

Note that in both cases, the exponent of decay may be the same but only the constants a and b differ.

Theorem 3 *The problem "Decay of Probability Differences" is BQP-complete.*

We prove this theorem by showing that the problem is BQP-hard and is contained in BQP.

5.1 "Decay of Probability Differences" is BQP-hard

To see that every problem in BQP can be reduced to "Decay of Probability Differences" we consider the adjacency matrix $\tilde{A}$ obtained from the matrix A as described in Section 4. Adopting the notation used there, we have $|q\rangle := |0\rangle \otimes |j\rangle$ and $|r\rangle := |1\rangle \otimes |j\rangle$ and label the corresponding vertices by q and r, respectively and obtain in straightforward analogy the following equality:

$$\begin{aligned} c_{qr}(t) &= \langle q|e^{-\mathcal{L}t}|q\rangle - \langle q|e^{-\mathcal{L}t}|r\rangle \\ &= \sqrt{2}\langle\psi^-|e^{-\mathcal{L}t}|q\rangle \\ &= \langle\psi^-|e^{-\mathcal{L}t}|\psi^-\rangle \\ &= \langle\psi^-|e^{-(4\cdot\mathbf{1}_{2N}-\tilde{A})t}|\psi^-\rangle \\ &= \langle j|e^{-(4\cdot\mathbf{1}_N-A)t}|j\rangle\,. \end{aligned} \tag{15}$$

We need some properties of the spectral measure induced by A and $|j\rangle$ to prove that "Decay of Probability Differences" is BQP-hard. They are obtained from Section 3 after taking into account the rescaling factor $\sqrt{2}$ (see the end of the section) and read:

1. the largest eigenvalue in the support of the spectral measure is $\sqrt{2}$ and the second largest is $\sqrt{2}\cos(\pi/M)$, and
2. the probability of obtaining the eigenvalue $\sqrt{2}$ is equal to $|\alpha_0|^2/M$.

Set $\mu := 4-\sqrt{2}$ and $\nu := 4-\sqrt{2}\cos(\pi/M)$ which are equal to the smallest and second smallest eigenvalue, respectively, that occur in the spectral measure induced by $4\cdot\mathbf{1}_N - A$ and $|j\rangle$. Using these eigenvalues, eqs. (15) imply

$$c_{qr}(t) \geq \frac{|\alpha_0|^2}{M}e^{-\mu t}$$

and

$$c_{qr}(t) \leq \frac{|\alpha_0|^2}{M}e^{-\mu t} + e^{-\nu t}\,.$$

Choose the time instant $T := \ln(6M)/(\nu-\mu)$. In this case, the bounds are

$$c_{qr}(T) \geq \frac{|\alpha_0|^2}{M}e^{-\mu T}$$

and

$$c_{qr}(T) \leq \frac{|\alpha_0|^2 + 1/6}{M}e^{-\mu T}\,.$$

Note that T increases only polynomially with M since $\nu-\mu$ scales inverse polynomially with M. Taking into account that $|\alpha_0|^2 \leq 1/3$ if $x \in L$ and $|\alpha_0|^2 \geq 2/3$ otherwise, we have for $\mathbf{x} \in L$

$$c_{qr}(T) \leq \frac{1}{2M}e^{-\mu T}\,,$$

and for $\mathbf{x} \notin L$

$$c_{qr}(T) \geq \frac{2}{3M} e^{-\mu T} .$$

This proves that we can reduce the question whether $\mathbf{x} \in L$ to the estimation of $c_{qr}(T)$.

5.2 "Decay of Probability Differences" is in BQP

In strong analogy to Section 4, the quantity of interest, which is here $c_{qr}(T)$, can be written as an expectation value

$$\begin{aligned} c_{qr}(T) &= \langle q|e^{-\mathcal{L}T}|q\rangle - \langle q|e^{-\mathcal{L}T}|r\rangle \\ &= \langle \psi^-|e^{-\mathcal{L}T}|\psi^-\rangle , \end{aligned} \qquad (16)$$

where the last equation follows (in analogy to Subsection 4.2) from the symmetry of the graph and not, as in the preceding paragraph, from setting $|q\rangle := |0\rangle \otimes |j\rangle$. The last expression in eq. (16) is an expectation value of a random experiment where the observable $\mathcal{L}$ is measured and the result λ is converted to $\exp(-\lambda t)$. To show that "Decay of Probability Differences" is in BQP we rescale $\mathcal{L}$ to $\mathcal{L}/b$ where b is a polynomial upper bound of the norm of $\mathcal{L}$. We have, for instance, $\|\mathcal{L}\| \leq 2d$ since the norm of $\tilde{A}$ is given by its degree d [17]. From the promise saying that the probability differences decay with $O(\exp(-\mu t))$ it follows that the decomposition of $|\psi^-\rangle$ contains only $\mathcal{L}$-eigenvectors with eigenvalues in $[\mu, \infty]$, i.e., we have only eigenvalues of $\mathcal{L}/b$ in $[\mu/b, \infty]$. We define $f : [\mu/b, \infty] \rightarrow \mathbf{R}^+$ with $f(x) := \exp(-x\, bT)$. Its Lipschitz constant is $K = bT \exp(-\mu T)$. Moreover, we have $\|f\|_\infty = \exp(-\mu T)$. Lemma 2 guarantees that we can efficiently estimate the expectation value of $f(\mathcal{L}/b)$ up to any desired inverse polynomial multiple of $(bT + 1)\exp(-\mu T)$. Since b and T are both polynomial, we can obtain an accuracy being any desired inverse polynomial multiple of $\exp(-\mu T)$. This is sufficient to solve "Decay of Probability Differences".

6 A QCMA-complete mixing problem

The complexity class QCMA, which is one possible quantum analogue of the classical class NP [18] can be obtained by modifying Definition 2 "slightly". Roughly speaking, we change the problem by not asking whether a *given state* $|\mathbf{x}, \mathbf{0}\rangle$ is accepted by the circuit Y_r in the sense that the output qubit is with high probability $|1\rangle$ after applying Y_r to the state. Instead, the problem is whether there *exists* a basis state that is accepted. In this case, this basis state is called a "witness" for the decision problem. The input string $\mathbf{x}$ does not define the *input state* for the circuit. Instead, it defines the circuit $Y_{\mathbf{x}}$ itself. More precisely, we have:

Definition 5 (Complexity Class QCMA)
A language L is in QCMA if there is a uniformly generated family $(Y_{\mathbf{x}})_{\mathbf{x}}$ of circuits (where $\mathbf{x}$ runs over the problem instances) acting on $r + l \in O(\mathrm{poly}(|x|))$ qubits such that the following statements are true:

If we define for every $r+l$-qubit basis state $|\mathbf{y}, \mathbf{0}\rangle$ the $r+l-1$-qubit states $|\psi_{\mathbf{x},\mathbf{y},0}\rangle$ and $|\psi_{\mathbf{x},\mathbf{y},1}\rangle$ by

$$Y_{\mathbf{x}}|\mathbf{y}, \mathbf{0}\rangle = \alpha_{\mathbf{x},\mathbf{y},0}|0\rangle \otimes |\psi_{\mathbf{x},\mathbf{y},0}\rangle + \alpha_{\mathbf{x},\mathbf{y},1}|1\rangle \otimes |\psi_{\mathbf{x},\mathbf{y},1}\rangle \,,$$

then we have:

1. *For every $\mathbf{x} \in L$ there is a "witness" $\mathbf{y}$ such that*
$$|\alpha_{\mathbf{x},\mathbf{y},1}| \geq 2/3 \,.$$
2. *For every $\mathbf{x} \notin L$ one has*
$$|\alpha_{\mathbf{x},\mathbf{y},1}| \leq 1/3$$
for every $\mathbf{y} \in \{0,1\}^r$.

Then we find:

Theorem 4 (QCMA-Complete Mixing Problem)
The following problem is QCMA-complete:

Given a regular sparse graph G on $2N$ nodes such that there exists an automorphism of G that exchanges all nodes $2j$ with $2j+1$ for $j = 0, 1, \ldots, N-1$. Let $\mu > 0$ and $b < a < 1$ be two positive numbers with $1/a, 1/b, 1/(a-b) \in \mathrm{polylog}(N)$ and $T \in \mathrm{polylog}(N)$ be some time instant.

Moreover, let $\tilde{N} \leq N$ be given with the promise that for all $j \leq \tilde{N}$ we have $c_{2j,2j+1}(t) \in O(\exp(-\mu t))$. Decide if either

1. *there is a number $j \leq \tilde{N}$ with*
$$c_{2j,2j+1}(T) \geq a\, e^{-\mu T}$$
or

2. for all $j \leq \tilde{N}$ *we have*

$$c_{2j,2j+1}(T) \leq b\, e^{-\mu T}\,.$$

To show that the problem is QCMA-hard we construct the graph $G_{\mathbf{x}}$ corresponding to a given $Y_{\mathbf{x}}$ according to Section 4, but keep in mind that the input string *for the circuit* (i.e., the potential witness) is here called $|\mathbf{y},\mathbf{0}\rangle$ instead of $|\mathbf{x},\mathbf{0}\rangle$. We reorder the nodes such that the states $|2j\rangle$ correspond to the states $|0\rangle \otimes |\mathbf{y},\mathbf{0}\rangle$ and the states $|2j+1\rangle$ to $|1\rangle \otimes |\mathbf{y},\mathbf{0}\rangle$ for $j = 0, 1, \dots, \tilde{N}$, where $\tilde{N}$ is chosen appropriately. Section 5 describes in detail how (1.) and (2.) in the above theorem correspond to the cases that the state $|\mathbf{y},\mathbf{0}\rangle$ is accepted or not by the circuit. Hence we have for each $\mathbf{x}$ a graph such that a pair $(2j, 2j+1)$ of nodes exists with $j \leq \tilde{N}$ and slow decay of probability differences if and only if there exists a witness $\mathbf{y}$ for the QCMA-problem.

To see that the problem is in QCMA we recall from the preceding section that we can efficiently determine $c_{2j,2j+1}(t)$ on the appropriate scale by estimating appropriate expectation values when applying the phase estimation procedure to the corresponding states

$$\frac{1}{\sqrt{2}}(|2j\rangle - |2j+1\rangle)\,. \tag{17}$$

The numbers j are therefore the potential witnesss: $\mathbf{x}$ is in L if and only if there exists a j which leads to slow decay of probability differences. We have now to construct a circuit where the values j define the possible input basis states.

We define a quantum register with $\lceil \log \tilde{N} \rceil + 1$ qubits where we identify each state (17) with

$$\frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) \otimes |j\rangle\,.$$

Assume we have already constructed a quantum circuit on $\lceil \log \tilde{N} \rceil + 1 + r$ qubits (with some appropriate r) describing the whole phase estimation procedure including the post-processing of the outcomes with the function f and the repeated sampling. This construction is rather technical, but in principle straightforward. Now we modify the circuit such that it accepts only those j with $j \leq \tilde{N}$. Finally, we add a Hadamard gate acting on the left component such that the state can be initialized to $|0\rangle$ instead of the superposition $|0\rangle - |1\rangle$. We define the correspondence

$$|0\rangle \otimes |j\rangle \otimes |0 \cdots 0\rangle \equiv |\mathbf{y},\mathbf{0}\rangle\,,$$

where j is now allowed to run over all values $0, 1, \ldots, 2^{\lceil \log \tilde{N} \rceil}$ instead of only $0, 1, \ldots, \tilde{N}$. We have now obtained a circuit for which there exists a witness $\mathbf{y}$ (defining r bits of the $r+l$-qubit basis state as input for $Y_{\mathbf{x}}$) iff there exists a pair $(2j, 2j+1)$ with $j \leq \tilde{N}$ that leads to slow decay.

7 Conclusions

We have constructed BQP-complete problems concerning the mixing properties of classical random walks. Roughly speaking, the problems are to estimate how fast the difference between the probability of being at different nodes decays in discrete and in continuous-time random walks. Given that the quantum computer is more powerful than the classical computer in the sense that $BPP \neq BQP$ we have hence shown that the quantum computer is also more powerful in analyzing certain mixing properties of classical random walks.
